Abstract

Integrated surface/subsurface models for simulating the thermal hydrology of permafrost-affected regions in a warming climate have recently become available, but computational demands of those new process-rich simulation tools have thus far limited their applications to one-dimensional or small two-dimensional simulations. We present a mixed-dimensional model structure for efficiently simulating surface/subsurface thermal hydrology in low-relief permafrost regions at watershed scales. The approach simplifies the full three-dimensional system to a two-dimensional overland thermal hydrology system with a family of one-dimensional vertical columns, where each column represents a fully coupled surface/subsurface thermal hydrology system without lateral flow. The overland thermal hydrology system is then operator split, incrementally updating lateral surface fluxes with no sources to redistribute mass and energy horizontally, followed and update including sources and sinks to couple to the columns. We show that the approach is highly scalable, supports subcycling of different processes,

and compares well with the corresponding fully three-dimensional representation at significantly less computational cost. These advances enable state-of-the-art representations of freezing soil physics to be coupled with thermal overland flow and surface energy balance at scales of 100s of meters. Although developed and demonstrated for permafrost thermal hydrology, the mixed-dimensional model structure is applicable to integrated surface/subsurface thermal hydrology in general.

Keywords: Mixed-dimensional model, Permafrost thermal hydrology, Integrated surface/subsurface flow modeling, Arctic

1. Introduction

Approximately 23% of the land surface in the Northern Hemisphere is underlain by continuous permafrost (91-100% frozen area), and another 17% is occupied by discontinuous permafrost (50-90% frozen area) [1, 2]. A massive
5 amount of organic carbon is stored in those regions [3, 4], which are warming at a rate considerably faster than the rest of the planet [5, 6, 7]. As the soils in that region warm, they have the potential to transform from a net sink to a net source of carbon to the atmosphere, which could increase the concentration of carbon in the atmosphere and in turn lead to further increase in the temperature (e.g.
10 [8]). Further, thawing and the resulting degradation of permafrost can cause significant changes in the surface and subsurface thermal hydrology and eventually can substantially alter the Arctic tundra ecosystems [9, 10, 11, 12, 13].

Those potential impacts and feedbacks in the terrestrial Arctic have motivated the development of increasingly sophisticated tools for simulating permafrost dynamics in a warming climate. Such simulations can help to better
15 understand the consequences of soil warming and responses of tundra ecosystems to warming trends, and further expose the effects of permafrost degradation on surface and subsurface thermal hydrology. However, simulating permafrost dynamics in a complex and coupled surface/subsurface thermal hydrological environment is a challenging task, especially at larger spatiotemporal scales [14].
20

A comprehensive review of the modeling efforts of the surface and subsurface can be found in [15]. Early research efforts focused on one-dimensional simulations for fundamental understanding of infiltration in cold climates; see, for example, [16, 17, 18]. Similar one-dimensional approximations have been adopted
 25 as coarse-scale models in global land surface models [19, 20, 21, 13]. Two-dimensional simulations with simplified physics (i.e. saturated conditions, subsurface only) have been used for understanding evolution of field-scale groundwater systems [22, 23], but do not represent key unsaturated zone processes that are needed to understand active layer dynamics and decomposition of soil
 30 organic matter. It is worth pointing out that mathematical models with limited complexity, reduced dimensionality, and relatively coarse spatial resolutions provide some insight into permafrost dynamics but fail to represent important processes such as cryosuction, lateral surface and subsurface flows, and advective heat transfers. Simulations with more mechanistic representations of surface and
 35 vadose zone process in three-dimensions are essential to accurately capture the potential impacts of permafrost thawing on the surface and subsurface thermal hydrology and the resulting effects on the carbon cycle.

Two- and three-dimensional models with explicit physics-based representations of ice/liquid/gas partitioning in the vadose zone [24] have only recently
 40 started to appear. Painter [2011] developed the three-phase, two-component model MarsFlo which has been used in Mars [26] and Earth permafrost studies [27]. Karra et al. [2014] simplified that subsurface freezing-soil thermal hydrology representation by ignoring gas advection and implemented that Richards-like approximation in the highly parallel PFLOTRAN [29] code. Kumar et
 45 al. [2016] used that implementation in three-dimensional microtopography-resolving thermal hydrology simulations of polygonal tundra. Those computer codes are all subsurface-only models; that is, they do not represent surface flows and surface energy balance. Painter et al. 2016 recently introduced the Arctic Terrestrial Simulator, which uses a sophisticated multiphysics management frame-
 50 work [32] to couple the three-dimensional subsurface representation of [28] with a two-dimensional non-isothermal surface flow model, surface energy balance

with and without snow, and a simple snow distribution model.

Despite the significant progress in developing integrated surface/subsurface permafrost thermal hydrology models, significant challenges remain in moving
55 to climate-relevant spatiotemporal scales. One of the challenges is that the integrated system is numerically stiff because of the highly dynamic surface system [31] and the ice-liquid phase transition [33], which often results in relatively small time steps to achieve convergence. Small time steps are not problematic in one-dimensional simulations because a well-designed simulation tool will re-
60 cover the time step quickly after a convergence failure. However, a small time step becomes problematic in large three-dimensional runs because it becomes increasingly likely that, at any given time, at least one computational cell will be experiencing a phase change and thus a small time step. The other major challenge is tracking thaw-induced subsidence. Traditional hydrological simulators
65 are mainly designed to conduct three-dimensional simulations, however, deformations in a three-dimensional simulation are not easy to track due to mesh tangling and can be computationally expensive; further, poor mesh quality may raise questions about the accuracy of the results.

To address the aforementioned challenges, we present a mixed-dimensional
70 modeling strategy for process-rich simulations of integrated surface and subsurface thermal hydrology in tundra systems with low topographic gradients. The approach is intended for spatial scales intermediate between microtopography-resolving fine-scale simulations and the scale of an Earth system model grid cell. We demonstrate with simulations of polygonal tundra, large and carbon-rich re-
75 gions of northern Siberia, Alaska, and Canada where soil cracking has led to the formation of subsurface ice wedges that honeycomb the subsurface and tessellate the land surface into polygonal patterns. Rather than solve a fully three-dimensional subsurface system tightly coupled to surface processes as in [31], we take advantage of physical insights gained from fine-scale simulations and
80 approximate the integrated surface/subsurface dynamics with mutually independent 1-D columns, each associated with an ice wedge polygon. The columns are then sequentially coupled to a surface thermal flow system, solving the sur-

face problem in an operator-split manner. This mixed-dimensional modeling approach is motivated by fine-scale simulations at the ice-wedge polygon scale that showed that differences in the thermal conditions among centers, rims and troughs of ice-wedge polygons are largely equilibrated by lateral heat transport during summer such that the system behaves similarly to a one-dimensional system on seasonal time scales. Mixed-dimensional model structures have been used previously in simulations of variably saturated flow at watershed scales, in particular to couple multiple 1-D unsaturated (vadose) zone representations to a two- or three-dimensional saturated zone; for example see [34, 35, 36]. Here we apply the mixed-dimensional model structure to an integrated surface/subsurface flow system including surface and subsurface thermal processes and evaluate the accuracy and computational advantages of the approximation.

The paper is organized as follows: Section 2 highlights the Advanced/Arctic Terrestrial Simulator (ATS) and the Arcos multiphysics management framework, within which we implemented our approach. Section 3 presents some fine-scale simulation results and analysis that motivated the approach. In Section 4 we introduce our mixed-dimensional modeling approach, loosely coupled scheme and the ATS refactoring strategy. To illustrate the performance and efficiency of our modeling strategy, in Section 5 we compare our numerical results with the three-dimensional simulations based on strong coupling, and present speedup and scalability of the new technique. Concluding remarks and future research are offered in Section 6.

2. The ATS Software

We implemented our mixed-dimensional modeling strategy in open-source parallel software known as Amanzi-ATS [37] (or simply ATS). Amanzi-ATS is the result of extending the flow and reactive transport simulator Amanzi [38] by adding an advanced multiphysics management system known as Arcos [32]. Arcos is key to managing the complex spatial structures used here. It was originally built to manage couplings among process models (denoted process

kernels and abbreviated as PKs), which may be selected at runtime. A PK encapsulates the mathematical representation of a particular physical process or coupled set of processes; PKs are coupled together through Multiprocess
 115 Coordinators MPCs. An MPC is regarded as a PK by MPCs at higher levels in the tree, thus allowing complex hierarchical model structures to be built dynamically at runtime. In this work, we used Arcos to coordinate not only process kernels but also subdomains of the larger spatial domain.

Amanzi, and by extension ATS, uses the Trilinos [39] framework for parallel
 120 infrastructure. An unstructured mesh framework [40] is included for interacting with the computational mesh. General polyhedral meshes are supported. Discretization accuracy is maintained on the potentially distorted grids through the use of the mimetic finite difference (MFD) method [41, 42]. The backward Euler method is used for time stepping with a Nonlinear Krylov Acceleration
 125 (NKA) method [43, 44] to solve the resulting discretized residual equations.

The initialism ATS may refer to either the Advanced Terrestrial Simulator, which is the general capability, or the Arctic Terrestrial Simulator, which is one particular configuration [31], depending on context. The Arctic Terrestrial Simulator configuration solves strongly coupled surface energy balance, and sur-
 130 face and subsurface thermal hydrology with freeze/thaw dynamics. This work extends the ATS to work with a multicolumn spatial structure.

3. Motivation: Results from Fine-scale Simulations

This mixed-dimensional approach is motivated by the results of fine-scale, two-dimensional simulations on vertical cross-sections across ice-wedge polygons
 135 at the Barrow Environmental Observatory. The simulations coupled a surface energy balance model potentially including snow, snow distribution models, models for thermal overland flow including phase change, and a recently developed three-phase subsurface thermal hydrology model. The soil properties were calibrated against borehole temperature data in a previous study [45]. The
 140 simulations were forced with meteorological data for the site. Those simulations

used an unstructured mesh that conforms to surface topography derived from lidar measurements. Horizontal mesh resolution is approximately 0.25 m. Vertical resolution is 0.02 cm at the surface and gradually increases with depth. Details on boundary conditions and the spinup process can be found in [31].

145 Snapshots of ice and liquid saturation indices in cross-section across two ice-wedge polygons are shown in Fig. 1. These snapshots are for October 15, 2013, which is during the fall freeze-up. During this period, the rims of the ice-wedge polygons are significantly colder than the centers and troughs because the thermally insulating snowpack is smaller on the rims. Previous one-dimensional
150 simulations [46] have shown that thermal differences caused by differences in snow depth lead to differences in active layer thickness, the depth of the annual thaw. However, in the two-dimensional simulations shown here, the active layer thickness shows little variation across the polygon (Fig. 2). Although transient differences in subsurface temperature occur due to differences in snow depth, soil
155 moisture content, and albedo, lateral heat transport is sufficient to equilibrate those differences by the time of maximum thaw. Thus, the active layer thickness, which is a primary control on the annual carbon decomposition rates, is not directly affected by microtopographic position within an ice-wedge polygon in cases where organic matter is relatively uniform. This lack of sensitivity suggests
160 a model structure where the ice-wedge polygon becomes the unit computational cell on the surface.

4. An Intermediate-scale Model

Recognizing the lack of sensitivity to lateral, subsurface flow described above, we derive an intermediate-scale model to leverage this simplification. This
165 model has two components: a spatial structure that combines one-dimensional and two-dimensional domains, and an operator splitting scheme that decouples the columns by solving lateral flow on the surface system independently of the sources and sinks of mass and energy which couple the surface and subsurface systems. We describe those aspects in this section, followed by a discussion of

Figure 1: Results from two-dimensional fine-scale modeling. Shown are snapshots of ice saturation index and liquid saturation index in cross-sections across two ice-wedge polygons.

Figure 2: Active layer thickness from fine-scale modeling. Note that the mesh resolution here is 2cm , and the discontinuities reflect jumps between cells of the mesh.

the refactoring strategy used to implement this model within the ATS.

4.1. Mixed-Dimensional Modeling Approach

To build an intermediate scale model, we first tessellate the land surface into N surface cells, where each cell in the surface mesh corresponds to an ice-wedge polygon. Custom mesh generation tools are then used to construct a 3D mesh by extruding each of the surface polygons vertically into the subsurface, introducing soil layering, etc. This 3D mesh represents the entire domain of interest and is referred to as the primary mesh. For the purpose of this model, each tessellated ice-wedge polygon, along with the volume of soil directly below it, is extracted as a single, one-dimensional (in the z -direction), column of soil. On each column, vertical flow of mass and transport of energy are solved, and on each column's surface, a (local) surface balance is performed to determine the net source of mass and energy into the system. These columns are then coupled through lateral surface flow, which quickly moves water and energy throughout the domain. We note that strong (globally implicit) coupling of the surface-to-subsurface fluxes are critically important for mass and energy conservation and accuracy of the system through strong nonlinearities.

Figure 3: An illustration of the independent 1D subsurface columns coupled to the overland system.

4.2. Operator Splitting Scheme

Due to this needed strong coupling between the surface and subsurface, the above mixed-dimensional strategy alone still results in a computational expensive system of equations. The tight coupling results in the need to solve all the columns and the surface flow equations simultaneously. To break this system, we develop a two-stage operator-split strategy for the surface flow and energy equations. Under this strategy, we split the lateral fluxes from the coupling fluxes, incrementally advancing one and then the other. In the first stage of the splitting, lateral fluxes are allowed to redistribute water and energy across the surface domain with no sources or sinks. This stage is hereafter called the “overland system.” Then, in a second update, the coupling fluxes and columnar subsurface may be solved implicitly, but independently of every other column. Each column consists then of the subsurface thermal hydrology, surface energy balance, and surface ponding and energy exchange fluxes with no lateral flow. This stage is hereafter called the “column-surface system.” This splitting is

shown schematically in Fig. 5. For the sake of clarity, we will refer to the pressure and temperature fields after the first stage as “overland-flow” pressure and temperature, while those after the second step will be called “subsurface” and “column-surface” pressures and temperatures.

205

4.3. Model Implementation with ATS and Arcos

This implementation of this strategy requires significant software infrastructure and refactoring support. First, and not trivially, physics and simulation data must be entirely modular and encapsulated, so that multiple instances of each physics process can be instantiated, allowing separate solution on multiple domains. Next, coupling these many processes on many domains requires a flexible, hierarchical coupling framework. Much of this was supported by Amanzi-ATS’s multiphysics library, Arcos[32]. Arcos represents physics on these domains as a hierarchical PK tree which shows how the processes are coupled on and across these domains, as illustrated in Fig. 4. The PK tree consists of individual conservation equations, strong (globally implicit) couplers, and weak (sequential) couplers highlighted in blue, light cyan, and orange colors, respectively. In our approach, the operator splitting between the overland and column-

215

surface systems happens at the top level weak MPC. The strong MPC (on the
 220 left at the second level) is the overland system; the weak MPC at the second level
 iterates over all the column subdomains. The PK-I, $I = 1, 2, 3, \dots, N$ denote an
 integrated system composed of surface energy balance, column-surface (a single
 cell for coupling fluxes) and subsurface (1D column) system. The tree attached
 to the black octagon shape is replicated across all PK-I, $I = 1, 2, 3, \dots, N$.

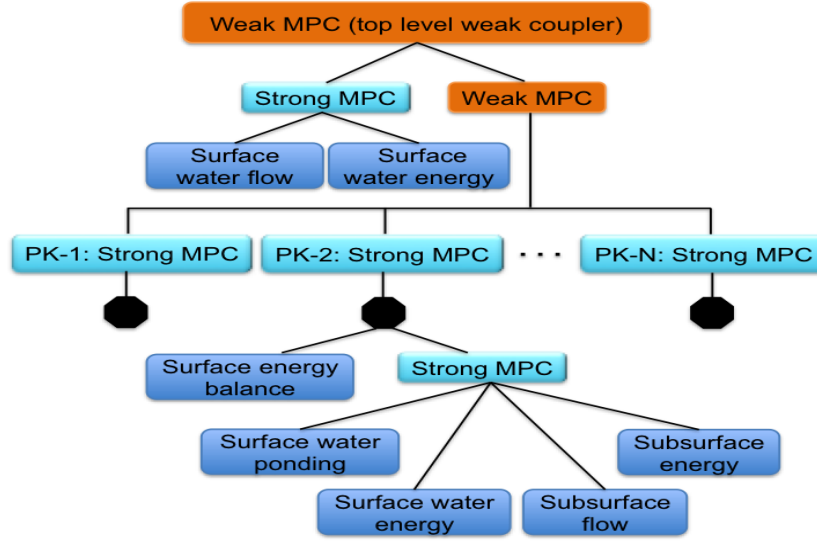

Figure 5: A customized hierarchical structure of the process kernels. Blue blocks highlights independent process models; Light blue blocks strongly coupled independent process kernels; Orange blocks represent weak couplers.

225 Refactoring of both ATS and its use of Arcos were needed to implement
 this strategy. To manage data encapsulation and replication, Arcos’s state ob-
 ject stores a dynamic, runtime-determined set of simulation data. Each data
 is identified by a unique key, e.g. “ponded_depth”, and a set of metadata in-
 cluding domain of applicability, mesh entity, number of degrees of freedom, etc.
 230 In order for each PK to be instantiated multiple times, that PK’s data was
 altered to enforce uniqueness of its keys by prefixing a domain identifier such as
 “column_0_surface-ponded_depth”. This refactoring allows multiple instances of
 any given PK, each attached to a different mesh representing a subdomain of

the primary mesh.

235 Furthermore, Amanzi-ATS relies on a meshing infrastructure, MSTK, [40]
which can generate meshes as subdomains or subsets of existing meshes. This
framework was extended to allow column meshes to be generated from an exist-
ing three-dimensional mesh. In this workflow, a surface mesh consisting of the
surface polygons are extruded vertically, following pre-determined soil horizon
240 structure, to create a 3D mesh. By insisting that the extrusion process works
only in the vertical, well-defined columns then exist in the the three-dimensional
mesh. At run-time, columns can then be identified, and extracted to form a
one-dimensional mesh. This mesh is altered to ensure it is a one-dimensional
submanifold of three-dimensional space, i.e. each cell has two faces, and all
245 face-normals are $\pm\hat{z}$. Once this is done, Amanzi-ATS's existing operators can
work on this mesh without changes. Furthermore, this mesh follows polygo-
nal ground, and therefore consists of stacked polygonal-prisms. Few mesh and
visualization libraries or utilities support this fully-unstructured mesh type; a
Silo[47] capability was added to to Amanzi-ATS's existing output options to
250 enable visualization of the resulting solution.

Each of these refactors was accomplished in reasonable time thanks to a
close adherence to computational software best practices. A series of unit and
regression tests were added for each new capability, and the existing regression
tests were updated with the domain prefixes. Version control enabled close col-
255 laboration on this process across multiple developers, and project-management
Kanban tools were used to ensure each developer in the workflow knew the
needs of the client code component. These best practices, along with the use
of libraries such as Silo, MSTK, and Arcos, greatly improved the efficiency of
what otherwise would have been a difficult development effort.

260 5. Results and Discussions

In this section, we present numerical results that highlights the accuracy and
efficiency of our modeling technique. At the development stage, several numeri-

cal experiments were performed to verify the physical behavior of the refactored modules (PKs) of the ATS, code verification details are presented in Appendix A. The spinup process (i.e., model’s initialization) has been described in detail in [31].

5.1. Numerical Results – A Comparative Study

To demonstrate the accuracy of our modeling technique, we compare numerical results of the mixed-dimensional model against a fully coupled three-dimensional simulations that act as a benchmark for our simulations. The domain under consideration has surface elevation varying between 4.14-4.62 m, is 40 m deep, and enclosed by a rectangle in the horizontal plane 173×160 m²; see Fig. 6. This domain is a part of the low-gradient polygonal tundra in Barrow, Alaska and consist of 75 ice wedge polygons. As highlighted in Fig. 6, we select five spots (based on different elevations) to perform a location-based comparison of the numerical results of the two schemes.

Figure 6: An illustration of the five spatial locations on 75 polygons cluster for location-based comparison of the two schemes. Location 1: Outlet. Location 2: High elevated spot. Location 3-4: Intermediate elevation spots. Location 5: Lowest elevation spot.

In addition to evaluating the quality of our mixed-dimensional approach for the Barrow tundra, we also want to understand when it will give inaccurate

results. Because our modeling strategy is based on a loosely coupled scheme and neglects subsurface lateral flow between ice wedge polygons, it should eventually become inaccurate if the topographic relief is sufficiently large. To identify the range of applicability, we consider three variants of the surface topography. We use the following equation to exaggerate the surface topography,

$$\bar{Z} = \alpha(Z - \mu) + \mu. \quad (1)$$

Here \bar{Z} is the exaggerated elevation, Z is the original elevation with mean μ , and α is the exaggeration parameter. Equation (1) preserves the mean while the standard deviation depends on the value of α and is given in meters by 0.14α .

280 The coefficient in front of α is the standard deviation of the original elevation Z – in our case Z correspond to the domain shown in Fig. 6. Our three variants correspond to $\alpha = 1, 3$, and 5. The value $\alpha = 1$ corresponds to the original topography. We expect the model to give promising results for simulating low-gradient polygonal tundra, and believe that the values of α we choose provide
285 sufficient variation across a domain of 100s of meter. Our numerical experiments confirm a high agreement between the results of the mixed-dimensional model and the 3D model at all selected location for all three α values. Figs. 7 and 8 compare the subsurface water saturations and temperatures, respectively, at locations 1 and 5 and for $\alpha = 1$. The accuracy of our results for the Barrow
290 topography ($\alpha = 1$) is evident. The surface ponded depths and temperatures obtained with the two models are depicted in Fig. 9 and 10, respectively. As expect, our results fit the 3D model’s results very well. We see the same level of agreement at the other locations as well, but we are not showing them here. In Fig. 11 we plot the mean annual thaw depth at five locations for the three
295 variants, $\alpha = 1, 3$, and 5. We use the annual mean of the thaw depth rather than the maximum thaw depth (i.e. the active layer thickness) because the mean annual thaw depth depends on both the duration of thaw and maximum thaw depth. Thus it is a direct measure of soil available for decomposition, averaged over the year. Not surprisingly, as the value of α increases the mean
300 annual thaw depth deviates from the results of the 3D model to some extent,

but we still see the results of the mixed-dimensional model agree well with the corresponding benchmark solution. The consistency of our numerical results with the fully coupled 3D simulations confirm the appropriateness of this approximated scheme.

Figure 7: Comparison of the subsurface water saturation at locations 1 and 5 during the summer.

305 5.2. Speedup Study

We discuss speedup and parallel efficiency for two spatial domains, one with 75 polygons as depicted in Fig. 6 and a larger one consisting of 468 ice-wedge polygons, as shown in Fig 12. The surface ponded depth and temperature during the snowmelt in 2012 are presented in Fig. 13 for the 468 polygon domain. Fully
310 coupled 3D simulations at such a scale are computationally very expensive.

We highlight two aspects of the efficiency of this modeling approach: (i) how the simulation time decreases in comparison with three-dimensional simulations, and (ii) how efficiently it scales with number of processes.

Fig. 14 compares the computational time of the multidimensional strategy
315 versus the three-dimensional solution for the domain consisting of 75 columns.

Figure 8: Comparison of subsurface temperature at locations 1 and 5 during the summer.

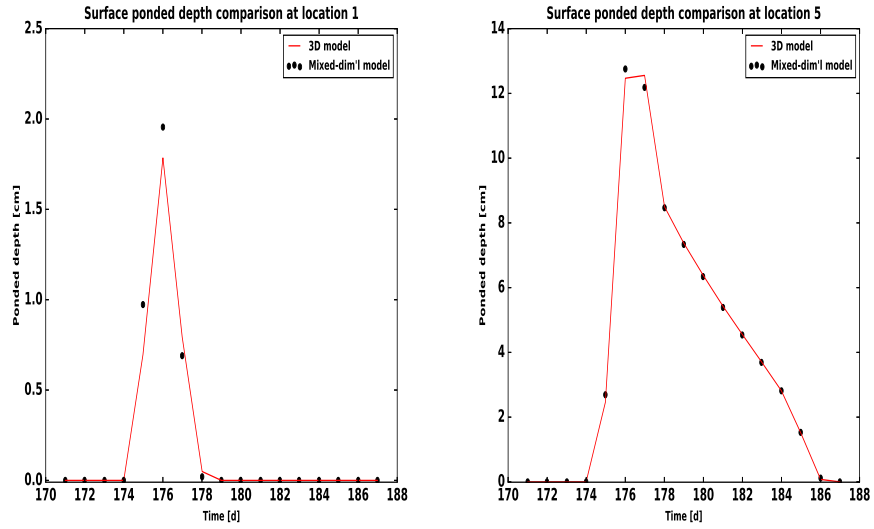

Figure 9: An illustration of the surface ponded depths of the two schemes at locations 1 and 5 when the snow melt starts.

Figure 10: An illustration of the surface temperature of the two schemes at location 1 for the entire year.

It can be seen that for a fixed number of processors, the computational time decreases by a factor of about four with the multidimensional technique. This is a huge computational advantage without sacrificing numerical accuracy.

We show parallel strong scaling for the aforementioned domains in Fig. 15. Speedup of the smaller domain is significantly less than the linear ideal; this is caused by communication overhead in the overland-flow system. Without consideration of the overland-flow system, the problem is perfectly parallel. To minimize communication between the overland-flow system and the column systems, the overland-flow mesh is partitioned so that a column and the coincident mesh cells on the overland-flow system reside on the same processor. If there are too few columns per processor, the interprocessor communication for the overland-flow system becomes the limiting factor despite the lower computational burden for the overland-flow system compared with the columns. As expected, the scaling is better for a larger domain. Scaling is close to linear up to about 16 cores, which corresponds to about 30 columns per core.

Figure 12: A watershed at Barrow, Alaska.

5.3. Subcycling Process Kernels

One advantage of sequentially coupling different PKs, as opposed to a fully coupled approach, is that sequential coupling makes subcycling possible. With subcycling, individual PKs take their own time step rather than a global time step. The independently evolving PKs are then synchronized on a larger time step. The idea is to assign a suitable local time-step to each subdomain rather than one single global time-step. It is a very convenient approach for simulating permafrost type regions because a relatively small time step may be required when a cell is going through a phase change. Without subcycling, a timestep failure or small timestep caused by phase change in a single cell results in a small global time step. With subcycling, the effects of that phase transition are limited to a single column. Our mixed-dimensional modeling approach efficiently allows subcycling PKs because we discretize subsurface as independent columns/subdomains. Thus, the subdomains can advance in time with their preferred time-steps until they hit the synchronized time. Fig. 16 displays per-

Figure 13: Simulation results of the mixed-dimensional model. Showing the surface ponded depth and temperature during the snowmelt of 2012.

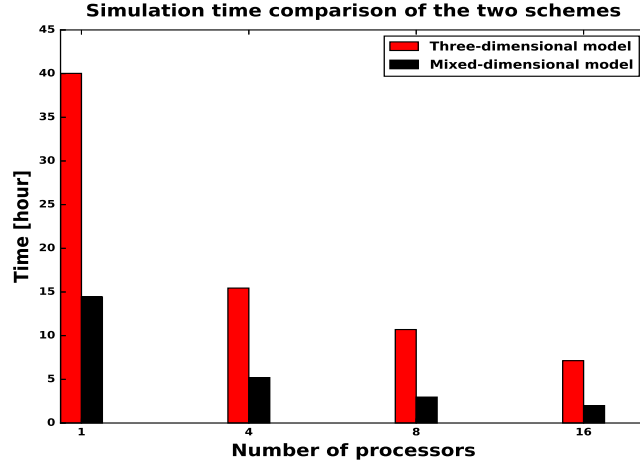

Figure 14: A comparison of the computational time taken by the mixed-dimensional and 3D models.

centage reduction in the simulation time for the domains consisting of 21, 75, and 468 polygons. With the increase in the number of subsurface columns the computational time decreases, and we see up to 40% reduction in the computational time in comparison with simulations without subcycling. The choice of the synchronization time is crucial, and requires further optimization, which will be studied in future work.

6. Conclusions and Future Work

Our intermediate-scale model for integrated surface/subsurface thermal hydrology of low-relief permafrost-affected regions is constructed from two components: a mixed-dimensional spatial structure that is based on discretizing the subsurface as independent columns that are indirectly coupled through a two-dimensional surface system, and an operator splitting scheme for coupling the column domains to the surface system. The spatial structure was motivated by fine-scale simulations of permafrost regions. This is the first demonstration of advanced representations of freezing soil physics coupled to overland thermal flow and surface energy balance at scales of 100s of meters.

Figure 15: An illustration of the speedup study of a simulation with 75-polygon cluster (top) and 468 polygons barrow watershed (bottom).

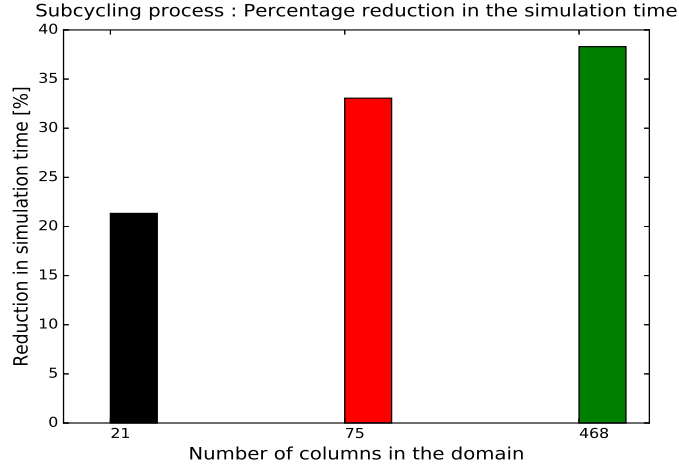

Figure 16: (Subcycling PKs) Percentage reduction in the computational time for the domains consisting of 21, 75 and 468 polygons.

An operator splitting algorithm is used to advance our mixed-dimensional model. First, we solve a two-dimensional surface thermal hydrology system that spatially distributes mass and energy, and initializes the system of the second
 365 step. The second step solves a family of independent one-dimensional columns, where each represents an integrated system of the subsurface, surface ponding and surface energy balance. That step updates the 2D surface system of the first step for the next iteration.

We compared our numerical results to the conventional scheme of a fully 3D
 370 subsurface that is strongly coupled to a surface system to demonstrate the efficiency and accuracy of our modeling approach. The fully coupled results act as a benchmark for our scheme. Numerical results show our scheme closely approximates the fully coupled system but is significantly more efficient. The scheme also allows for subcycling of individual subdomains, which further improves the
 375 numerical efficiency.

This work is part of a larger effort to provide process-rich, watershed-scale simulations capability for permafrost regions. A next step would be to incorporate a subgrid model to represent the effects of variations of topography below

our discretization unit of the ice wedge polygon. Another future direction is
 380 to represent thaw-induced subsidence. Thawing of permafrost and melting of
 massive subsurface ice can cause differential subsidence, leading to dynamic
 microtopography (low-centered polygons can transform to high-centered poly-
 gons) [48, 49], substantial changes in hydrology and soil moisture, and altered
 drainage networks, thus potentially transforming a dry region to a wetland
 385 ecosystem [50, 51]. This modeling strategy is designed to tractably represent
 thaw-induced subsidence. Representing subsidence in one dimension is signif-
 icantly easier than a fully three-dimensional representation because mesh tan-
 gling and other mesh quality issues arise in a fully three-dimensional dynamic
 mesh but are avoided in one dimension. Indeed, simulations of thaw-induced
 390 subsidence on a single one-dimensional integrated surface/subsurface system has
 already been demonstrated [14]; the work described here will allow the same
 techniques to be used at scale with many columns coupled to an overland flow
 system. Lastly, refactoring ATS not only supports subdomain modeling tech-
 niques but is also potentially useful future extensions. We can efficiently imple-
 395 ment and independently test many process representations (physical, chemical,
 biological and geological processes) as PKs and let them interact through MPCs.

Although we mainly focus on simulating the thermal hydrology of degrad-
 ing permafrost, elements of the work presented here have greater applicability.
 A hybrid spatial structure mixing one-dimensional representations of the va-
 400 dose zone with two-dimensional representations of the saturated zone and over-
 land flow system are important approximations in watershed modeling. This
 operator-split scheme of Fig. 5 is broadly applicable to those systems and to
 integrated surface/subsurface simulations, in general. This mixed-dimensional
 representation may be used as an alternative to a fully coupled system or as a
 405 way of accelerating the time-consuming task of spinup. In addition, this work
 demonstrates the advantages of Arcos or other multiphysics management frame-
 works in greatly simplifies the process of building models with hybrid spatial
 structure.

Appendix A. Numerical Experiments – Code Verification

We have performed a series of tests at the development stage for code verifica-
tion, and compared our results against numerical solution of three-dimensional
model. The 3D results serve as a benchmark for our scheme. In 3D models
420 the surface and subsurface systems are strongly coupled and solved implicitly.
Since our model required major refactoring of the ATS, so individual pieces of
the code were deeply tested before integration – they are listed below:

- Problem Test 1 (Subsurface Flow): We consider multiple subsurface columns
with flat top surface – each column is an independent domain. Put water
425 table below the surface, infiltrates and fills the subsurface columns.
- Problem Test 2 (Surface and Subsurface Flow only): This is an extension
of the Test 1. We put water table below the surface. Water infiltrates and
fill subsurface columns prior to surface ponding.
- Problem Test 3 (Subsurface Thermal Hydrology): We add energy equation
430 to Test 1. Initially, establish water table close to the surface, and start
freezing from below. The frozen subsurface columns are thawed from the
top.
- Problem Test 4 (Surface and Subsurface Thermal Hydrology): In this
test, we incorporate surface thermal hydrology into Test 3. A warm rain
435 precipitation thaws the subsurface columns, saturate them and afterwards
water ponds on the surface.

- Problem Test 5 (Surface Energy Balance, Surface and Subsurface Thermal Hydrology): A fully integrated surface and subsurface processes test. We introduce an energy balance equation to Test 4. An initially established ice table below the surface has been thawed by warm rain, incoming-short radiation and air temperature.

Due to symmetry in the domains of above numerical tests, that is, the subsurface columns are copies of each other and surface is flat, we get identical results and compare very well with its corresponding three-dimensional simulation results. Passing all the above tests conclude refactoring of the ATS a success. In the preceding discussion, we consider general polyhedra due to the polygonal structure of the Arctic landscape.
